Synthesis of Combinational Logic Circuits using Genetic Algorithms

Cecília Reis, J. A. Tenreiro Machado

Institute of Engineering of Porto
Dept. of Electrical Engineering, Portugal

Abstract

This paper proposes a genetic algorithm for designing combinational logic circuits and studies three different case examples: the one-bit full adder, the four-bit parity checker and the two-bit multiplier. The objective of this work is to generate a functional circuit with the minimum number of gates.

Index Terms: Circuit design, combinational circuits, genetic algorithms, computer-aided design

1.Introduction

In the last decade genetic algorithms (GAs) have been applied in the design of electronic circuits, leading to a novel area of research called Evolutionary Electronics (EE) or Evolvable Hardware (EH) [1]. EE considers the concept for automatic design of electronic systems. Instead of using human conceived models, abstractions and techniques, EE employs search algorithms to develop good designs [2].
One decade ago Sushil and Rawlins [3] applied GAs to the combinational circuit design problem. They combined knowledge-based systems with the GA and defined a genetic operator called masked crossover. This scheme leads to other kinds of children that can not be achieved by classical crossover operators.
John Koza [4] adopted genetic programming to design combinational circuits. His goal was the design of functional circuits through AND, OR and NOT logic gates.
In the sequence of this work, Coello, Christiansen and Aguirre [5] presented a computer program that automatically generates high-quality circuit designs. They use five possible types of gates (AND, NOT, OR, XOR and WIRE) with the objective of finding a functional design that minimizes the use of gates other than WIRE.
Miller, Thompson and Fogarty [6] applied evolutionary algorithms for the design of arithmetic circuits. The technique was based on evolving the functionality and connectivity of a rectangular array of logic cells, with a model of the resources available on the Xilinx 6216 FPGA device.
Kalganova, Miller and Lipnitskaya [7] proposed a new technique for designing multiple-valued circuits. The EH is easily adapted to the distinct types of multiple-valued gates, associated with operations corresponding to different types of algebra, and can include other logical expressions. This approach is an extension of EH method for binary logic circuits proposed in [6].
In order to solve complex systems, Torresen [8] proposed the method of increased complexity evolution. The idea is to evolve a system gradually as a kind of divide-and-conquer method. Evolution is first undertaken individually on a large number of simple cells. The evolved functions are the basic blocks adopted in further evolution or assembly of a larger and more complex system.

More recently Hollingworth, Smith and Tyrrell [9] describe the first attempts to evolve circuits using the Virtex Family of devices. They implemented a simple 2-bit adder, where the inputs to the circuit are the two 2-bit numbers and the expected output is the sum of the two input values.
A major bottleneck in the evolutionary design of electronic circuits is the problem of scale. This refers to the very fast growth of the number of gates, used in the target circuit, as the number of inputs of the evolved logic function increases. This results in a huge search space that is difficult to explore even with evolutionary techniques. Another related obstacle is the time required to calculate the fitness value of a circuit [10]. A possible method to solve this problem is to use building blocks either than simple gates. Nevertheless, this technique leads to another difficulty, which is how to define building blocks that are suitable for evolution.
Timothy Gordon [11] suggests an approach that allows evolution to search for good inductive bases for solving large-scale complex problems. This scheme generates, inherently, modular and iterative structures, that exist in many real-world circuit designs but, at the same time, allows evolution to search innovative areas of space.
Following this line of research, this paper proposes a GA for the design of combinational logic circuits. This paper is organized as follows. Section 2 introduces the problem and the adopted GA, as well as the encoding of the circuit as a chromosome, the genetic operators and the fitness function. Section 3 presents the simulation results and their comparison. Finally, section 4 presents the main conclusions.

2. Problem and Algorithm Formulation

In this work are considered combinational logic circuits specified by a truth table. These circuits can have multiple inputs and multiple outputs and the goal is to implement a functional circuit with the least possible complexity. For that purpose, it is defined a set of logic gates and are generated circuits with components of that specific set.
In this study we define four gate sets, each one with different types of logic gates, as presented in table I. Gset 6 is the most complex set, Gset 4 and Gset 3 are medium complexity sets and Gset 2 is the simplest one.
For each gate set the GA searches the solution space of a function through a simulated evolution aiming the survival of the fittest strategy. In general, the best individuals of any population tend to reproduce and survive, thus improving successive generations. However, inferior individuals can, by chance, survive and also reproduce [12]. In our case, the individuals are digital circuits, which can evolve until the solution is reached (in terms of functionality and complexity).
EH systems develop chromosomes that encode the functional description of a given circuit. As with many GA applications, the resulting circuit is the phenotype as it comprises several smaller logic cells or genotypes. The adopted terminology reflects the conceptual similarity between EH, natural evolution and genetics [13].

TABLE I - GATE SETS

Gate Set	Logic gates
Gset 6	{AND,OR,XOR,NOT,NAND,NOR,WIRE}
Gset 4	{AND,OR,XOR,NOT,WIRE}
Gset 3	{AND,OR,XOR,WIRE}
Gset 2	{AND,XOR,WIRE}

In the GA scheme the circuits are encoded as a rectangular matrix (*row* × *column* = $r \times c$) of logic cells as represented in figure 1a.
Each cell is represented by three genes: <*input1*><*input2*><*gate type*>, where *input1* and *input2* are one of the circuit inputs, if they are in the first column, or one of the previous outputs, if they are in other columns. The *gate type* is one of the elements adopted in the gate set. The chromosome is constituted by as many triplets of this kind as the matrix size demands. For example, the chromosome that represents a 3 × 3 matrix is depicted in figure 1b.

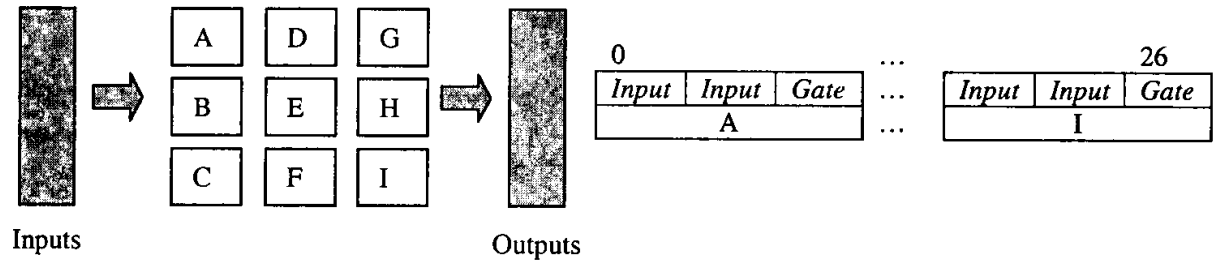

Fig.1a) - Example of a matrix 3 × 3 to represent a circuit.
b) Chromosome for the example of figure 1a.

The initial population of circuits (strings) is generated at random. The search is then carried out among this population. The three different operators used are reproduction, crossover and mutation, as described in the sequel.
In what concern the reproduction operator, the successive generations of new strings are reproduced on the basis of their fitness function. In this case, it is used a tournament selection [12] to select the strings from the old population, up to the new population.
For the crossover operator, the strings in the new population are grouped together into pairs at random. Single point crossover is then performed among pairs. The crossover point is only allowed between cells to maintain the chromosome integrity.
The mutation operator changes the characteristics of a given cell in the matrix. Therefore, it modifies the gate type and the two inputs, meaning that a completely new cell can appear in the chromosome. Moreover, it is applied an elitist algorithm and, consequently, the best solutions are always kept for the next generation.
To run the GA we have to define the number of individuals to create the initial population *P*. This population is always the same size across the generations.
The crossover rate *CR* represents the percentage of the population *P* that reproduces in each generation. Likewise *MR* is the percentage of the population *P* that mutates in each generation. Usually, in order to achieve the population evolution, *CR* is high (*e.g.*, 80%-95%) and, to prevent population diversity, *MR* is low (*e.g.*, 1%-5%). In our case, to evolve the circuits, we adopt $P = 3000$ individuals, $CR = 95\%$ and $MR = 5\%$.
The calculation of the fitness function *F* is divided in two parts f_1 and f_2 that measure the functionality and the simplicity, respectively. Firstly, we compare the output produced by the GA-generated circuit with the expected values, according with the truth table, on a bit-per-bit basis (*i.e.*, f_1). Once the circuit is functional, the GA tries to generate circuits with the least number of gates. The index f_2, that measures the simplicity, is increased by one (zero) for each *wire* (gate) of the generated circuit, yielding:

$$f_{10} = 2^{ni} \times no, f_2 = f_2 + 1 \text{ if } gate\ type = wire,\ F = \begin{cases} f_1, & F < f_{10} \\ f_1 + f_2, & F \geq f_{10} \end{cases} \quad (1)$$

where *ni* and *no* represent the number of inputs and outputs of the circuit.

3. Simulation Results

This section shows the implementation of three different combinational logic circuits, namely, a one-bit full adder, a four-bit parity checker and a two-bit multiplier.
The first case study is a one-bit full adder (OFA) circuit, with a truth table with 3 inputs {A, B, C_{in}} and 2 outputs {S, C_{out}}. In this case, the matrix has a size of $r \times c = 3 \times 3$, and the length of each string representing a circuit (*i.e.*, the chromosome length) is $CL = 27$.
Due to the stochastic nature of the GAs, for each gate set we performed several simulations. Figure 2a shows the fitness function F *versus* the number of generations N to achieve the solution.
The best gate set is the one that presents the solution after the least number of generations N with the higher final fitness function F. Since the one-bit full adder has $ni = 3$ and $no = 2$, it results $f_{10} = 16$ and $F \geq 20$.

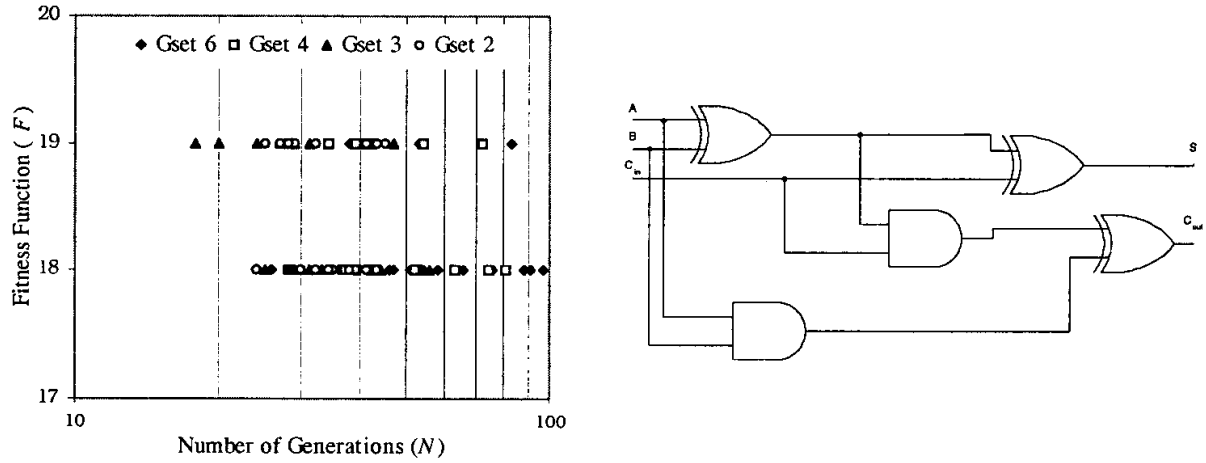

Fig.2a) - Fitness function F *versus* number of generations N to achieve the solution.
b) GA generated One-bit Full Adder circuit.

We can see that, in this case, the best gate sets are Gsets 3 and 2, because they lead to a smaller average number of generations N_{av} and the best average final fitness function F_{av}. The best resulting circuits have final fitness function $F = 19$ as shown in figure 2b.
The second case study is a four-bit parity (even) checker (FPC) circuit, with a truth table having 4 inputs {A_3, A_2, A_1, A_0} and 1 output {P}. The size of the matrix is $r \times c = 4 \times 4$ and the chromosome length is $CL = 48$.
Figure 3a shows the simulation results in terms of number of required evolving generations N and final fitness function F, for each gate set.
In this case $ni = 4$ and $no = 1$, resulting $f_{10} = 16$ and $F \geq 24$. The best results are obtained with Gset2. Figure 3b illustrates the schematic of the best circuit with an $F = 25$.
The third case study is a two-bit multiplier (TM) circuit. Therefore the truth table has 4 inputs {A_1, A_0, B_1, B_0} and 4 outputs {C_3, C_2, C_1, C_0}. The matrix, for this example, is $r \times c = 4 \times 4$ dimensional, and the chromosome as size $CL = 48$.

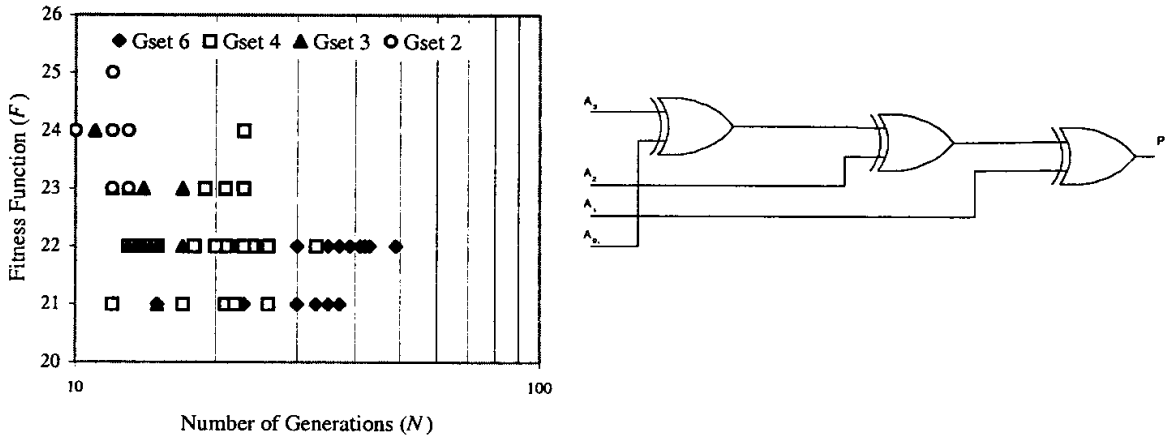

Fig.3a) - Fitness function F *versus* number of generations N to achieve the solution.
b) GA generated Four-bit Parity Checker circuit.

For the two-bit multiplier we have $ni = 4$ and $no = 4$, leading to $f_{10} = 64$ and $F \geq 72$. Once again we conclude that Gset2 is the best gate set for generating the combinational logic circuits (figure 4a). The schematic of the best resulting circuit ($F = 72$) is shown in figure 4b.

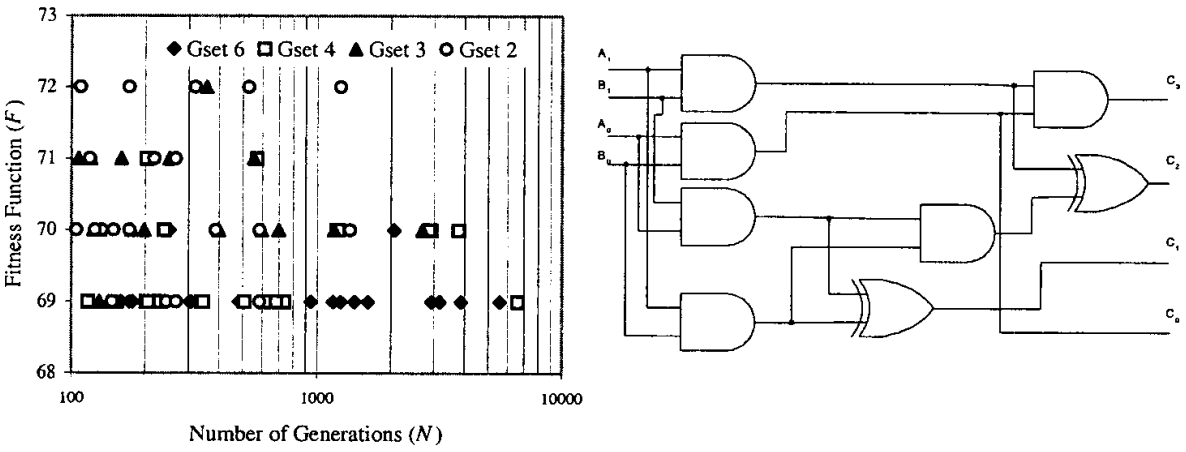

Fig.4a) Fitness function F *versus* number of generations N to achieve the solution.
b) GA generated Two-bit Multiplier circuit.

Comparing the three case studies through the required average number of generations N_{av} and the resulting average fitness function F_{av} (table II) we conclude that, independently of the circuit complexity, the best results occur for a reduced Gset. This conclusion has similarities with the RISC vs CISC processor dilemma but, before establishing a final conclusion, more extensive experiments with other circuits are required.

TABLE II - GA RESULTS

Circuit	OFA		FPC		TM	
Gate Set	N_{av}	F_{av}	N_{av}	F_{av}	N_{av}	F_{av}
Gset 6	72.45	18.15	32.55	21.70	1699.00	69.15
Gset 4	53.65	18.35	20.40	21.95	1183.05	69.50
Gset 3	32.40	18.45	13.754	22.65	432.40	70.25
Gset 2	34.86	18.57	7.95	23.95	362.35	70.45

Another issue that emerges with the increasing number of circuit inputs and outputs is the scalability problem. Since the truth table grows exponentially, the GA computational burden to achieve the solution increases dramatically. This problem lies on the gate-based strategy for Boolean implementation. Consequently, more efficient implementation alternatives are currently under evaluation.

4. Conclusions

This paper proposed a GA for designing combinational logic circuits given a set of logic gates. The final circuit is optimised in terms of complexity (with the minimum number of gates).
For all the case studies the GA has proved to be efficient, even when the number of outputs in the truth table increases. It is also visible that the performance of the GA increases as the complexity of the gate set decreases. Experiments show that we have better results with Gset 2, that is, the simplest set that we have adopted in this study.
Motivated by the results future investigation will address the design of sequential logic circuits and the feasibility *versus* complexity and convergence of the resulting circuits.
